Gear Tooth Scoring Design Considerations for Spur and Helical Gearing

by

Peter Lynwander
Breeze-Eastern Corp., Union, N.J.

Introduction

High speed gearing, operating with low viscosity lubricants, is prone to a failure mode called scoring. In contrast to the classic failure modes, pitting and breakage, which generally take time to develop, scoring occurs early in the operation of a gear set and can be the limiting factor in the gear's power capability.

Scoring is a form of surface damage on the tooth flank, which occurs when overheating causes the lubricant film to become unstable allowing metal to metal contact. Local welding is initiated and the welded junctions are torn apart by the relative motion of the gear teeth resulting in radial score marks. Figs. 1, 2 and 3 illustrate degrees of the scoring phenomenon. Light scoring, which does not progress, may be acceptable, but heavier scoring can destroy the tooth profile and lead to pitting and breakage. Also, scoring can result in noisy operation and the release of metallic particles into the lubrication system.

The American Gear Manufacturers Association Aerospace Gearing Committee has been investigating the scoring phenomenon for many years. AGMA Information Sheet 217.01, "Gear Scoring Design Guide for Aerospace Spur and Helical Power Gears," October, 1965, is a widely used method for predicting scoring based on Professor Blok's flash temperature index concept. The Scoring Information Sheet is currently being updated and this paper is a review of the changes and additions being made.

In addition to the flash temperature approach, the minimum film thickness concept will be covered in the new publication. In the minimum film thickness approach, an elastohydrodynamic film thickness is calculated and compared to the asperity height to determine whether the lubricant film is adequate.

Flash Temperature Index

The critical total temperature hypothesis (flash temperature index) appears to be the most reliable method of analysis presently used to predict scoring. It states that scoring will

MR. PETER LYNWANDER is the Director of Engineering at Breeze-Eastern Corporation, Union, New Jersey. His experience encompasses 25 years of design, analysis and development of mechanical systems, and includes establishing computer programs for the analysis and optimization of gear configurations. Mr. Lynwander received his B.S. and M.S. degrees from the University at Bridgeport, Connecticut, and he is a registered Professional Engineer. He has been active on several AGMA committees. Mr. Lynwander has authored numerous publications concerning gearing, seals and clutches including Gear Drive Systems published by Marcel Dekker Inc. This paper was written while Mr. Lynwander was employed by American Lohmann Corp., Hillside, N.J.
Now you can have quality-assured master gages through our computerized gear and spline QC system

Master gears which remain constant for years

Now M & M Precision Systems offers complete designing and manufacturing of gear gages used in all types of gear inspection procedures...setting, rolling and sizing masters—spur and helical. Accuracy levels required for master reference, QC inspection or production grades are assured through testing with our computer-controlled Model 2000 QC System—the industry standard for automated gear and spline testing.

We also make quality-assured spline gages

Our plug gages and ring gages are manufactured under the same strict inspection procedures as our master gears. We make setting, alignment, and GO/NO GO masters in a variety of configurations such as sector, involute, serrated, tapered, and helical.

Strict, automated quality control is inherent in every manufacturing stage and, upon part completion, every aspect of material stability and dimensional accuracy is checked again so that our master gears will give you years of constant service. Before shipping, individual product records of every product are reviewed and certified. Calibration certificates, traceable to the National Bureau of Standards are supplied.

Other related products now available include:

- Comparators
- Rotolock Arbors
- Master Worms
- Helical Spline Plugs and Rings
- Index Plates
- Broaching Rings

For quotations or applications information, write or call M & M Precision Systems, 300 Progress Rd, West Carrollton, OH 45449, (513) 859-8273. Ask for our QC Master Gage brochure.

Shown above is the 2000 QC system at work checking a master gear. The blow up at the right shows the simple system transducer scanning a master gear for true universal gear inspection. Also shown is a printout of an involute check made under total computer control.

CIRCLE A-6 ON READER REPLY CARD
occurs when a critical total temperature, which is characteristic of the particular combination of lubricant and gear material, is reached.

\[ T_f = T_b + \Delta T \]

where

- \( T_f \) = Flash temperature index, \(^\circ\)F
- \( T_b \) = Gear blank temperature, \(^\circ\)F
- \( \Delta T \) = Maximum rise of instantaneous surface temperature in the tooth mesh above the gear blank's surface temperature.

The gear blank temperature is difficult to estimate. It may be significantly higher than the bulk oil temperature. The heat transfer capability of the gear must be considered in attempting to estimate this parameter.

Often the blank temperature is approximated as the average of the oil temperature entering and leaving the gearbox.

One form of the fundamental flash temperature index formula is:

\[ T_f = T_b + \frac{C_f f W (V_1 - V_2)}{\sqrt{V_1} + \sqrt{V_2}} \frac{B_c}{2} \]

where

- \( C_f \) = Material constant for conductivity, density and specific heat
- \( f \) = Friction coefficient
- \( V_1 \) = Rolling velocity of pinion at point of contact, fps
- \( V_2 \) = Rolling velocity of gear at point of contact, fps
- \( B_c \) = Width of band of contact
- \( W \) = Specific loading, normal load divided by face width, lbs./in.

For steel on steel gears, taking \( C_f \) as 0.0528, \( f \) as a constant 0.06 and adding a term taking surface finish into account the following equation results:

\[ T_f = T_b + \left( \frac{W_{te}}{F_e} \right)^{3/4} \left( \frac{50}{50 - S} \right) Z_t (n_p)^{1/2} \]

where:

- \( W_{te} \) = Effective tangential load, lbs.
- \( F_e \) = Effective face width (use minimum contact length for helical gears), in.
- \( S \) = Surface finish (after running in), RMS
- \( n_p \) = Pinion RPM
- \( Z_t \) = Scoring geometry factor

\[ Z_t = 0.0175 \left[ \sqrt{e_p} - \sqrt{\frac{N_p - e_g}{N_g}} \right] \left[ \cos \beta_g \right]^{3/4} e_{p_e}^{1/4} \]

Note: Use absolute value of \( Z_t \).
where \( e_p \) = Pinion radius of curvature, in.
\( e_g \) = Gear radius of curvature, in.
\( N_p \) = Number of pinion teeth (smaller member)
\( N_g \) = Number of gear teeth (larger member)
\( \varphi \) = Pressure angle, transverse operating

50

The 50 - s term was developed by Kelly\(^2\) in an experimental program using gears with surface finish in the range of 20-32 RMS. For gears with surface finish rougher than this range, if the computed value exceeds 3, a factor of 3 should be used. For gears with surface finishes finer than 20, the resulting computed factor may be conservative.

The term \( W_s \) must be adjusted to allow for the sharing of load by more than one pair of teeth. The following analysis, which modifies the tooth load depending on the position of the gear mesh along the line of action, was developed by Dudley using spur gears of standard proportions. If a more accurate prediction of tooth load sharing is available to the reader, it would be appropriate to use that analysis.

\[
W_s = K W_t
\]

where \( W_t \) = Tangential tooth load, lbs.

1. Unmodified tooth profiles

\[
K = \frac{1}{3} - \frac{1}{3} \left[ \frac{\theta + \theta_{LD}}{\theta_{L} + \theta_{LD}} \right]
\]

\( \theta_{LD} \leq \theta < \theta_{L} \)

\( K = 1.0 \)

\( \theta_{L} \leq \theta \leq \theta_{H} \)

\[
K = \frac{1}{3} + \frac{1}{3} \left[ \frac{\theta_{O} + \theta}{\theta_{O} + \theta_{H}} \right]
\]

\( \theta_{H} < \theta \leq \theta_{O} \)

2. Modified tooth profiles

A. Pinion driving

\[
K = \frac{6}{7} \left[ \frac{\theta - \theta_{LD}}{\theta_{L} - \theta_{LD}} \right]
\]

\( \theta_{LD} \leq \theta < \theta_{L} \)

\( K = 1.0 \)

\( \theta_{L} \leq \theta \leq \theta_{H} \)

\[
K = \frac{1}{7} + \frac{6}{7} \left[ \frac{\theta_{O} - \theta}{\theta_{O} - \theta_{H}} \right]
\]

\( \theta_{H} < \theta \leq \theta_{O} \)

B. Pinion driven by gear:

\[
K = \frac{1}{7} + \frac{6}{7} \left[ \frac{\theta - \theta_{LD}}{\theta_{L} - \theta_{LD}} \right]
\]

\( \theta_{LD} \leq \theta < \theta_{L} \)

\( K = 1.0 \)

\( \theta < \theta < \theta_{H} \)

\[
K = \frac{6}{7} \left[ \frac{\theta_{O} - \theta}{\theta_{O} - \theta_{H}} \right]
\]

\( \theta_{H} < \theta \leq \theta_{O} \)

where \( \theta \) = Any pinion roll angle (see appendix), radians

\( \theta_{LD} \) = Roll angle at the pinion limit (form) diameter, radians

\( \theta_{L} \) = Roll angle at the lowest point of single tooth contact on the pinion, radians

\( \theta_{H} \) = Roll angle at the highest point of single tooth contact on the pinion, radians

\( \theta_{O} \) = Roll angle at the pinion outside diameter, radians

A modified tooth profile would be one which has tip and/or flank relief rather than a true involute form.

The flash temperature index should be calculated at five specific points on the line of action and at several additional points of contact. The five specific points are:

1. Outside diameter of pinion
2. Highest point of single tooth contact
3. Pitch point (flash temperature rise will be zero since there is no sliding)
4. Lowest point of single tooth contact
5. Form (contact diameter) of pinion.

Fig. 4 is a typical plot of flash temperature rise along the line of action.

The most convenient way to generate a plot, such as shown in Fig. 4, is by the use of a computer program. By stepping through successive roll angles, the Flash Temperature Index can be calculated at many points. From Fig. 4 it can be seen that there will be two peaks, one during the arc of approach (pinion form diameter to pitch diameter) and one during the arc of recess (pinion pitch diameter to outside diameter). In order to achieve the minimum flash temperature index, the flash temperature rise in the arc of approach should be equal to the rise in the arc of recess. An optimum tooth design can be achieved by the use of long and short addendums. The computer program, starting with standard addendums (1/4 Diametral Pitch), automatically varies the pinion and gear addendums in defined increments until the optimum flash temperature is obtained. With the resulting long and short addendum designs of this nature, standard tooth thicknesses are no longer applicable. If standard tooth
thicknesses were utilized, an unbalance of bending stresses between pinion and gear would result. To optimize the bending stresses, the program enters a second iteration procedure which varies tooth thickness until bending stresses are balanced.

Fig. 5 presents the results of an aerospace industry survey\(^{(4)}\) correlating scoring to flash temperature index. From the data used in the study, it was assumed that a gear set with a calculated index of 276°F, or less, represents a low scoring risk. A calculated index ranging from 277°F to 338°F represents a medium scoring risk where scoring may or may not occur, and a calculated index of 339°F and higher represents a high scoring risk. The data presented in Fig. 5 reflects cases using SAE 9310 steel operating with MIL-L-7808 or MIL-L-23699 synthetic oil. The viscosity of these oils is approximately 4-6 centistokes at 200°F and 18-30 centistokes at 100°F. Mineral oils such as light turbine oils, used in high speed industrial applications, are more viscous and, therefore, can tolerate a higher flash temperature index.

The equation for the flash temperature index assumes a constant coefficient of friction of 0.06. If it is desired to calculate the coefficient of friction at each point on the line of action, the following equation can be used:\(^{(5)}\)

\[
f = 0.0127 \log_{10} \left[ \frac{3.17 \times 10^8}{\mu_v V_s V_t^2/W} \right]
\]

where

- \(f\) = Coefficient of friction
- \(\mu_v\) = Absolute viscosity, in centipoises
- \(V_s\) = Sliding velocity, ips
- \(V_t\) = Sum velocity, ips
- \(W\) = Specific loading, lbs./in.

The equation breaks down at the pitch point where the sliding velocity is 0.0 and the friction coefficient goes to infinity.

Using a variable coefficient of friction, the flash temperature index formula becomes:

\[
T_f = T_b + f \left[ \frac{W_{te}}{F_c} \right]^{3/4} \left[ \frac{50}{S - S_0} \right] Z_t \left( \frac{p_o}{P_d} \right)^{1/2}
\]

\[
Z_t = \frac{0.2917}{\cos \theta} \left[ \frac{e_p - e_g}{e_p + e_g} \right]^{1/4}
\]

**Scoring Criterion Number**

\[
\text{Scoring criterion number} = \left( \frac{W_t}{F_c} \right)^{3/4} \left( \frac{p_o}{P_d} \right)^{1/4}
\]

where:
- \(W_t\) = Tangential driving load, pounds
- \(F_c\) = Contacting face width inches
- \(p_o\) = Pinion RPM
- \(P_d\) = Diametral pitch

Table 1 gives scoring criterion numbers for various oils at various gear blank temperatures.

If the scoring criterion number is above the values shown in the table, there is a possibility that scoring will be encountered. The gear blank temperature can be taken as the average of the oil in and oil out temperatures.

**Minimum Film Thickness Criterion**

Scoring is a phenomenon that will occur when gears are operating in the boundary lubrication regime\(^{(6)}\) rather than with a hydrodynamic or elastohydrodynamic oil film separating the gear teeth. The film thickness can be calculated\(^{(7,8,9)}\) and compared to the combined surface roughness of the contacting elements to determine if metal to metal contact is likely to occur. A criterion used to determine the possibility of surface distress is the ratio of film thickness to composite surface roughness:

\[
\lambda = \frac{h_{min}}{\delta}
\]

\[
\delta = \sqrt{\delta_p^2 + \delta_g^2}
\]

where:
- \(\lambda\) = Film parameter
- \(h_{min}\) = Minimum oil film thickness, in.
- \(\delta_p\) = Pinion average roughness, RMS
- \(\delta_g\) = Gear average roughness, RMS

The "Partial Elastohydrodynamic" or "mixed" lubrication regime occurs if the film parameter, \(\lambda\), is between approximately 1 and 4. At higher values, full hydrodynamic lubrication is established and asperity contact is negligible. Below a \(\lambda\) of 1.0 there is a risk of surface distress.
The minimum elastohydrodynamic film thickness is calculated as follows: (Ref. 7 and 8):

\[ H = \frac{2.65(G)^{0.54} (U)^{0.70}}{(W)^{0.13}} \]

\[ H = \frac{h_o}{R} \] (Film thickness parameter)

\[ h_o \] = Minimum film thickness, in.

\[ R \] = Equivalent radius, in.

\[ R = \frac{e_p \pm e_g}{e_p} \] (+ external) \(- internal\)

\[ e_p \] = pinion radius of curvature, inches

\[ e_g \] = gear radius of curvature, inches

\[ G = \delta E' \] (Materials parameter)

\[ \delta = \text{pressure viscosity coefficient, in}^2/\text{lb} \] (Fig. 6)

\[ \frac{1}{E} = \frac{1}{2} \left[ \frac{1-\delta_1^2}{E_1} + \frac{1-\delta_2^2}{E_2} \right] \]

\[ \delta_1 = \text{pinion Poisson's ratio} \]

\[ \delta_2 = \text{gear Poisson's ratio} \]

\[ E_1 = \text{pinion Young's modulus} \]

\[ E_2 = \text{gear Young's modulus} \]

\[ W = W'/E.R \] (Load parameter)

\[ W' = \text{Specific loading, lbs/in.} \]

\[ U = \frac{1}{2} (v_1 + v_2) \mu_o \]

\[ \frac{E}{R} \]

\[ v_1 = w_p e_p = \text{rolling velocity of pinion at point of contact, in/\text{sec.}} \]

\[ v_2 = w_g e_g = \text{rolling velocity of gear at point of contact, in/\text{sec.}} \]

\[ w_p = \text{pinion angular velocity, rad/sec.} \]

\[ w_g = \text{gear angular velocity, rad/sec.} \]

\[ \mu_o = \text{absolute viscosity, Reyns (lb sec/in}^2) \]

\[ \mu_o = \frac{\rho Z_k}{6.9 (10^6)} \]

\[ e = \text{specific gravity (Fig. 7)} \]

\[ Z_k = \text{kinematic viscosity, centistokes (Fig. 8)} \]

**Closure**

An extensive survey of aerospace power gears operating with synthetic lubricants at high temperature revealed that calculated oil films were in the order of 0.000010 to 0.000020 inches. With surface roughness in the order of 20 RMS it can be seen that these gears are operating with \( \lambda \) less than 1.0; are in the boundary lubrication regime and, therefore, prone to scoring problems.

APPENDIX 1
Gearset Geometry for Calculating Flash Temperature Index

Table 2 shows the results of a computer analysis of a high speed gear set with standard addendums. The flash temperature index is the maximum flash temperature rise, \(71^\circ F\), plus the gear bulk temperature \(160^\circ F\). The index of \(231^\circ F\) presents a low scoring risk (Fig. 5) which could be slightly reduced by optimizing tooth proportions. The calculated coefficient of friction is significantly lower than the assumed value of 0.06 with a corresponding lower flash temperature rise. The calculated minimum film thickness is 0.000020 with a \(\lambda\) term of .71 indicating operation in the boundary lubrication regime.
